Abstract
This case report highlights the variety of wide complex tachycardias, and the need for their prompt management, in the growing population of patients with circulatory support devices. We present a case that demonstrates how a wide complex supraventricular tachycardia in a patient with a biventricular assist device can be safely and effectively targeted for treatment using percutaneous radiofrequency catheter ablation, allowing for clinical improvement, weaning of RVAD treatment, and discharge home with LVAD alone.

Introduction
With the increasing use of ventricular assist devices (VAD) as a bridge to transplant or as destination therapy, there have been more reports of the presence and implications of arrhythmias associated with such devices. This case report illustrates that although patients with underlying heart failure requiring VADs may have a high pretest probability of having ventricular tachycardia and ventricular fibrillation, one must also consider other etiologies for wide complex tachycardias, including supraventricular arrhythmias in the presence of baseline bundle branch block or rate-related aberration.

Case Report
A 54 year old man with a remote history of Hodgkin's lymphoma, treated with splenectomy and radiation in 1986, was transferred from an outside hospital for further management of acute cardiogenic shock. He initially presented to his primary doctor with chest pain and had an electrocardiogram (ECG) with anterior ST elevations concerning for acute myocardial infarction. He underwent coronary catheterization at the outside hospital, which showed a complete occlusion of the proximal left anterior descending artery as well as an unspecified circumflex artery lesion. During balloon angioplasty, the patient became hemodynamically unstable. The procedure was aborted and an intra-aortic balloon pump (IABP) was placed. At this time, he was transferred to our medical center's cardiac intensive care unit for further management.

Because of the severely reduced biventricular function and refractory cardiogenic shock despite the presence of an IABP, a biventricular assist device (BiVAD) was implanted. His post-operative course was complicated by acute renal failure requiring continuous veno-venous hemodialysis. He was also noted to have several episodes of wide complex tachycardias in the setting of a baseline non-specific intraventricular conduction delay. Several arrhythmias were identified, including ventricular tachycardia (VT) and ventricular fibrillation (VF) (see Figure 1), as well as atrial flutter with varying amounts of AV block (Figure 2). The patient was treated with esmolol, amiodarone, procainamide, and lidocaine for these arrhythmias. However, the patient continued to manifest one predominant wide complex tachycardia that complicated attempts to wean the patient from a BiVAD to a left ventricular assist device (LVAD) alone (Figure 3, left panel). Therefore, an electrophysiology study (EPS) and radiofrequency ablation was performed with the goal of stabilizing rhythm control and optimizing hemodynamic management.

Despite more pronounced AV block during previous episodes of atrial flutter (Figure 2), at EPS the arrhythmia was diagnosed as cavo-tricuspid isthmus-dependent atrial flutter with 2:1 conduction to the ventricle (Figure 3). During radiofrequency ablation to the cavo-tricuspid isthmus (CTI), the arrhythmia terminated to sinus rhythm. Moreover, further programmed ventricular stimulation did not result in inducible VT. After the atrial flutter ablation, the patient was maintained on oral amiodarone and metoprolol and did not have recurrence of any significant tachycardia through hospital discharge three weeks post-ablation. After sustained restoration of sinus rhythm and improvement in right-sided hemodynamics, the
patient’s right ventricular level of support was weaned, allowing for the right ventricular assist device (RVAD) circuit to be explanted and the patient to be discharged home with destination LVAD therapy.

Discussion
This case report highlights that even in patients with a high pretest probability of having VT/VF, it is important to consider other known causes of wide complex tachycardias that can contribute toward hemodynamic compromise. Studies have shown that patients with severe heart failure requiring VADs were more likely to have ventricular arrhythmias that negatively impacted survival and other outcomes. Nevertheless, it has also been demonstrated that atrial arrhythmias are fairly common in patients with VADs and have affected outcomes including mortality by a variety of proposed mechanisms. This case illustrated that in patients with VADs, the treatment not only of ventricular arrhythmias but also of supraventricular arrhythmias is important for longer term management, as ablation of the atrial flutter allowed for RVAD explantation and discharge home with destination LVAD.

The main etiologies of a wide complex tachycardia may include ventricular arrhythmias, supraventricular arrhythmias in the setting of underlying bundle branch block/intraventricular conduction defect or with rate-related aberrancy, or supraventricular arrhythmias with ventricular pre-excitation. While certain non-invasive diagnostic algorithms for distinguishing between ventricular or supraventricular sources of the arrhythmia have been suggested historically and reviewed more recently, there is still much inter-user variability among the algorithms, making them somewhat unreliable especially in the context of regular wide complex tachycardias. Furthermore, their utility in LVAD patients has not been established. The use of EPS to diagnose the arrhythmia is more invasive, but also provides definitive information as well as the potential for immediate and
effective treatment with ablation. Since EPS has been demonstrated to be safe in patients with VADs and can produce excellent results regardless of the etiology of the arrhythmia, it should be considered a safe adjunct or alternative to oral and parenteral antiarrhythmic treatments.

Patients with VADs can tolerate wide complex tachycardias including ventricular tachyarrhythmias more effectively from a hemodynamic standpoint. However, a known common presentation of ventricular arrhythmias is not sudden death, but rather acutely worsening right heart failure. Catheter ablation of ventricular arrhythmias has been shown to be safe in patients with VADs and can result in decreased symptoms and burden of antiarrhythmic medications. Nevertheless, atrial arrhythmias have previously been shown to be prevalent in patients with VADs with resultant increased signs and symptoms of right heart failure. We show in this case that effective control of atrial arrhythmias helped permit recovery of this patient's right ventricular function and ultimately allowed for explantation of the RVAD and discharge from the hospital.

Conclusion

As the use of mechanical assist devices for heart failure continues to expand, there remains much to be studied about the impact these devices have on arrhythmia prevalence and patient outcomes, and vice versa. This case demonstrates that: (i) VAD patients can sustain multiple wide complex tachycardias of different etiologies, including ventricular tachycardia, ventricular fibrillation, and supraventricular tachycardias such as atrial flutter with baseline intraventricular conduction defect or rate-related aberration; (ii) electrophysiology study and radiofrequency ablation of clinically deleterious wide complex tachycardias in VAD patients, including supraventricular tachycardias with rapid ventricular response, are possible and effective for rhythm control and can facilitate recovery and overall clinical outcome. In summary, consideration of supraventricular tachycardias in VAD patients with medically refractory wide complex tachycardias allows for relatively straightforward diagnosis and management with ablation, resulting in a significantly positive impact upon a patient's clinical course.
