Case

67 year old male with history of hypertension (HTN), diabetes mellitus (DM), and persistent atrial fibrillation (AF) who was being evaluated for aMAZE study underwent a Computed tomography angiography (CTA) for screening purposes. Left atrial appendage (LAA) was found to be missing [Figure 1] and patient had no previous history of surgical or percutaneous left atrial appendage exclusion.

Discussion

Left atrial appendage develops in 3rd -4th week of embryonic life from the left wall of the primary atrium and functions like a left atrium during the fetal life [Figure 2] [1]. In adults it is believed to function as a decompression chamber during elevated left atrial pressures including left ventricular systole or volume overload situations. It also contributes towards left atrial reservoir and contractile functions [2]. Its physiological and ultrastructural properties are distinct from the left atrium main chamber. Left atrial appendage (LAA) has particularly drawn attention in the last decade due to its potential role in the atrial fibrillation (AF) and thromboembolic phenomena. Ninety percent of thrombi, in the setting of non-valvular atrial fibrillation, are found in left atrial appendage [3] and around 27% of patients presenting for repeat ablation procedures have triggers in left atrial appendage [4]. Mechanical closure/isolation of LAA for stroke prevention is, therefore, a new trend in the world of electrophysiology. Congenital absence of left atrial appendage is very rare and its impact on electromechanical properties of left atrium are not known. But, of more interest and significance would be, its clinical implications for the patient with atrial fibrillation in terms of anticoagulation or even ablation procedures. These are the areas that would need further studies and/or thorough literature review of such cases, in order to get some answers.

Disclosures

None.
