Abstract
Body mass index (BMI) is a powerful predictor of death, type 2 diabetes (T2DM) and cardiovascular (CV) morbidity and mortality. Over the last few decades, we have witnessed a global rise in adult obesity of epidemic proportions. Similarly, there has been a parallel increase in the incidence of atrial fibrillation (AF), itself a significant cause of cardiovascular morbidity and mortality. This may be partly attributable to advances in the treatment of coronary heart disease (CHD) and heart failure (HF) improving life expectancy, however, epidemiological studies have demonstrated an independent association between obesity, diabetes and AF, suggesting possible common pathophysiological mechanisms and risk factors. Indeed, cardiac remodeling, haemodynamic alterations, autonomic dysfunction, and diastolic dysfunction have been reported in obese and diabetic cohorts. Moreover, diabetic cardiomyopathy is characterized by an adverse structural and functional cardiac phenotype, which may predispose to the development of AF. In this review, we discuss the pathophysiological and mechanistic relationships between obesity, diabetes and AF, and some of the challenges posed in the management of this high-risk group of individuals.

Introduction
Obesity, Metabolic Syndrome and AF Risk
The link between obesity and AF was first recognized in retrospective analyses of incident AF in peri-operative cardiac surgical patients.1-4 These early observations were subsequently supported by data from several large cohort studies. The first prospective study of incident AF was undertaken in subjects from the Framingham cohort, in which there was a 4-5% increase in AF risk for every unit increase in BMI, over a mean duration of 13.7 years.5 Furthermore, this association remained unchanged even after adjusting for myocardial infarction (MI), hypertension (HT) and diabetes (DM), and increased across the range of obesity. In the same study, obesity was also associated with an increase in left atrial diameter, a recognized precursor of AF. However, the relationship between BMI and AF was lost following adjustment for left atrial size, suggesting AF risk in obese subjects is mediated through left atrial enlargement, a finding which has also been reported in subjects with the metabolic syndrome (MetS).6,7

Indeed, left atrial enlargement is present in a significant proportion of obese adolescents and adults and is attenuated following weight reduction.8,9 In the MONICA/KORA study, age, obesity and HT were independently associated with left atrial enlargement over a ten-year period; obesity being the most powerful predictor (OR: 2.4 vs. 2.2; p<0.001) and the combination of obesity and HT demonstrated the greatest LA enlargement.10 Other large prospective studies have reported comparable AF risk, for example in the Danish Diet, Cancer and Health study of 47,589 individuals followed up over a mean duration of 5.7 years, the incidence of AF/flutter was 1.2%, two thirds of which occurred in males.11 The adjusted hazard ratios (HR) for AF/flutter were 2.35 (95% CI 1.70-3.25) and 1.99 (95% CI 1.31-3.02) in obese men and women respectively. In a recent meta-analysis, obesity was associated with a 49% increased risk of AF (RR 1.49, 95% CI 1.36-1.64) in 6 population studies, but no association was reported in post cardiac surgery studies (RR 1.02, 95% CI 0.99-1.06).12 Similarly, in the long term follow up of the Atherosclerosis Risk in Communities (ARIC) study cohort, 17.9% of incident AF was attributed to obesity. In a long term follow up study of Swedish men; BMI and BSA in youth were associated with AF risk with an increased risk of progression from paroxysmal AF to permanent AF.13 In the Women's Health Study of over 34,000 female healthcare professionals free of CVD, the investigators reported a linear relationship between BMI and AF characterized by a 4.7% (95% CI: 3.4-6.1% p<0.0001) increased risk of AF for every 1 unit increase in BMI.14 This association was maintained whichever classification of obesity was used and after adjusting for confounding variables and inflammatory markers. Importantly, a change in weight...
category during the first 5 years of follow up was associated with a corresponding change in AF risk. This risk was marginally greater in subjects who progressed from the non-obese (BMI ≤ 30) to obese (BMI ≥30) weight category than those who were obese at baseline and follow up (RR 1.41 vs. 1.32). Weight reduction from obese to non-obese was associated with a risk reduction to that of non-obese subjects at baseline. These findings would imply that AF risk in obese individuals is reversible, achievable through interventions such as weight reduction. Furthermore, the lower risk observed at follow up in the group who were obese at baseline supports the concept of an obesity paradox which has been reported in previous studies such as the Atrial Fibrillation Follow-Up Investigation of Rhythm Management (AFFIRM) trial in which obese patients with AF had favourable outcomes compared with their non-obese counterparts.15,16 Clearly, further studies are required to investigate this phenomenon.

Although there is considerable overlap with obesity, Met S is generally considered to be a constellation of risk factors specific to the development of atherosclerotic cardiovascular disease and T2DM and is characterized by abdominal obesity, dyslipidaemia, HT and glucose intolerance.17 Few robust studies have been carried out in MetS cohorts to assess AF risk. In the Niigata study, subjects with MetS had an increased risk of AF which was independently associated with age and obesity, irrespective of the definition of MetS used (AHA/NHLBI vs. NCEP-ATPIII).18 In multivariate models for individual components of the MetS, BMI and HT contributed the most to AF risk and interestingly, low HDL cholesterol was also strongly associated. In addition, AF risk was positively correlated with the number of MetS components exhibited, further supporting the notion that MetS simply represents a clustering of risk factors.19 In a recent study of the Framingham Offspring cohort, the relationship between insulin resistance (IR) and incident AF in non-diabetic subjects was investigated over ten years of follow up.20 Both adjusted (HR 1.27, 95% CI 0.92 to 1.76, p=0.15) and unadjusted (HR 1.10, 95% CI 0.83 to 1.45, p=0.52) analyses failed to demonstrate an association between IR and AF.

Although the mechanistic basis for the relationship between obesity, LA enlargement and AF is not completely understood, it is likely to be multifactorial involving haemodynamic disturbances, autonomic dysfunction and induction of the renin-aldosterone-angiotensin-system (RAAS), resulting in mechanical and electrical remodeling of the left atrium.

**Diabetes and AF Risk**

Several studies have reported an association between DM and AF.21,22 In the ARIC study, the incidence of AF in diabetic subjects was double that of non-diabetic subjects.23 Furthermore, DM but not pre-diabetes was associated with an increased AF risk (HR 1.35, 95% CI 1.14-1.60) which was independently associated with fasting glucose and HbA1c. In a recent meta-analysis, DM was associated with an increased AF risk (RR 1.39, 95% CI 1.10-1.75, p <0.001), which remained significant after correction for publication bias and multiple risk factors (RR 1.24, 95% CI 1.06-1.44, vs. 1.70, 1.29-2.22, p = 0.053).24

**Adipocytokines – the Link between Fat, Inflammation and AF**

C-reactive protein (CRP) levels are increased in patients with persistent AF compared to controls and subjects with paroxysmal AF (PAF), thus suggesting a possible link between inflammation and AF.25-27 A building literature supports the role of adipose tissue mediated inflammation and the development of AF. Recent work on visceral adipose tissue has focused on the role of epicardial fat in the pathogenesis of AF as epicardial fat thickness correlates strongly with visceral fat on magnetic resonance imaging.28-30 Individuals with permanent AF have a greater volume of epicardial fat compared with individuals with PAF, and those with either PAF or permanent AF have a greater volume of pericardial fat compared with controls.31 This difference is predominantly related to atrial adiposity as opposed to periventricular epicardial fat thickness, which is comparable between all groups.32 More specifically, adipose tissue thickness in the inter-atrial septum is positively correlated with BMI and left atrial volume and inversely correlated with plasma adiponectin levels.32 Epicardial fat thickness is associated with an increased risk of AF whereas pericardial fat is predictive of LA volume in addition to AF prevalence, severity and poorer outcomes following catheter ablation.33,34

The effects of epicardial fat on the heart are mediated through a group of cytokines produced by adipocytes known as adipocytokines which possess inflammatory, anti-inflammatory and vasoactive properties implicated in the pathogenesis of several cardiovascular diseases.30,35 Several adipocytokines have been associated with AF including adiponectin, resistin, a pro-inflammatory cytokine associated with insulin resistance, and more recently, YKL-40, a general marker of inflammation.36-38 Adiponectin levels are reduced in obesity and T2DM and increase following weight loss.39,40 Ybarra et al studied the relationship between LA size and adiponectin in obese subjects.41 Adiponectin levels significantly correlated with indices of glycaemia, insulin and lipids and were significantly lower in both obese subjects and in obese subjects with an enlarged LA. The association with LA size persisted after adjustment for the homeostasis model assessment of insulin resistance (HOMA-IR), age, sex, and LV mass. Few studies have investigated the relationship between adipocytokines and AF. In a study of the Framingham offspring cohort, plasma resistin concentration was significantly associated with incident AF (HR 1.17, 95% CI 1.02-1.34, p=0.028), however this relationship was lost after adjustment for CRP42 and adiponectin concentration did not predict incident AF. In contrast, adiponectin appears to have a protective effect following cardiac surgery.43,44 YKL-40 is associated with AF recurrence following catheter ablation, but did not predict successful cardioversion in patients with AF.45,46 In a Japanese study, adiponectin levels were elevated in patients with persistent AF compared to those with paroxysmal AF and controls.47 The significance of such findings is unclear and further studies are required to determine the relationship between adipocytokines and AF.

The association between inflammation and AF has also been established via mechanistic in vitro studies.26,48 Inflammatory changes have been observed in atrial tissue from patients with lone AF and at the cellular level, NAD(P)H oxidase activity and nitric oxide synthase uncoupling in the myocardium have been proposed as sources of free radicals contributing to oxidative stress in the atrial myocardium of patients with AF.49 Whole-cell patch clamp studies of pulmonary vein cardiomyocytes have demonstrated that TNF-α incubation leads to altered calcium homeostasis and enhanced arrhythmogenicity.50
Autonomic Dysfunction and the Atrial Substrate

Cardiac autonomic neuropathy (CAN) the commonest manifestation of diabetic autonomic neuropathy (DAN), may be present during the pre-diabetic phase, and is a strong independent risk factor for morbidity and mortality. This risk may be attributable to features of advanced CAN including sudden cardiac death (SCD), cardiac arrhythmias, silent myocardial ischaemia and lack of hypoglycaemia awareness. Hypoglycaemia has been associated with an increased mortality risk which may be attributable to the pro-arrhythmic effects of hypoglycaemia on the QT interval. However, despite the increased incidence of hypoglycaemia and mortality in the Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial, there were fewer atrial fibrillation deaths both during intensive treatment and following termination of this arm of the study. AF risk is increased in diabetic subjects and this risk increases with diabetes duration and worsening glycaemic control. Although the exact role of glycaemia in the progression of CAN is not fully understood, several large clinical trials have demonstrated the beneficial effects of glycemic control and multifactorial cardiovascular intervention on delaying the onset of CAN. CAN is also associated with coronary microvascular dysfunction and diastolic dysfunction in diabetic subjects.

The cardiac autonomic nerves play a key role in the regulation of heart rate and an imbalance in autonomic tone can give rise to electrophysiological effects which may predispose to the development of AF. The sino-atrial (SA) node and atrio-ventricular (AV) node are both influenced by autonomic tone, and vagal stimulation can result in marked changes in cardiac electrophysiology, including heterogeneous effects on the atrial refractory period (ARP), pacemaker activity and AV conduction. Increased vagal tone also contributes to the genesis of so called ‘vagal AF’, a phenomenon that is thought to play a key role in a subset of patients in whom primarily vagal abnormalities contribute to AF.

Sympathetic over-activity on the other hand, may precipitate AF and occurs following the induction of the RAAS. Increased levels of angiotensin II and decreased levels of the neuropeptide, substance P, are associated with post-operative AF incidence in patients undergoing CABG, thus implicating the role of sympathetic over-activity and reduced parasympathetic activity, respectively in the pathogenesis of AF. Despite the early promise for the use of RAAS inhibitors in the prevention of AF, subsequent trials and meta-analyses have shown no benefit. Another important manifestation of RAAS activation is myocardial fibrosis, which is mediated through pro-fibrotic agents such as angiotensin II and results in both electrical and mechanical remodeling of the left atrium predisposing to AF.

Neural remodeling is thought to play a crucial role in increased AF vulnerability in DM and experimental models have shown alterations in sympathetic nerves in the right atrium with AF being enhanced by adrenergic activation. Aberrant neurotransmission seems to be a key feature of arrhythmogenicity and a recently published study showed alterations in purinergic neurotransmission in the atria of diabetic rats. AF may also be provoked in individuals with PAF and normal autonomic function by isoprenaline implying enhanced platelet aggregation via synergistic action with adenosine diphosphate. Adiponectin also plays a role in platelet aggregation, as knock-out animal models exhibit enhanced thrombus formation which is reversed by the delivery of adenovirus-mediated adiponectin. Plasma adiponectin has been shown to be inversely correlated with platelet aggregation in patients with T2DM, HT or hypercholesterolaemia.

Interventions in AF

Stroke Risk in AF

The risk of thromboembolic complications and stroke in AF is non-linear. A number of risk factors have been identified that increase stroke risk in AF in a cumulative manner and have been incorporated into formal stroke risk stratification schemes to aid clinicians. Over the past decade, these schemes have had a modest predictive value for stroke and thromboembolism, especially when patients are categorized into low, moderate, and high risk groups. The main purpose for this risk stratification was to identify high-risk patients who may benefit from antithrombotic therapy.
risk patients who might benefit from oral anticoagulant therapy in spite of its relative inconvenience. These risk categories however are essentially artificial divisions of a continuous spectrum of stroke risk, especially in the presence of multiple stroke risk factors. As such, the 2010 European Society of Cardiology (ESC) guidelines relaxed the emphasis on categorizing patients into low, moderate or high stroke risk by promoting an approach based on individual risk factors.

To complement the simple and extensively used CHADS2 score (Congestive heart failure, Hypertension, Age >75 and Diabetes and Stroke/TIA) score, the ESC guidelines recommend the use of the newer CHA2DS2-VASc scheme97,98 emphasizing a more robust stroke risk assessment, and to help identify those who are truly ‘low risk’.

Unlike DM, obesity and MetS are not considered specific risk factors in such risk stratification schemes however there is some evidence to suggest they should. In a study examining the risk of left atrial thrombus in patients with AF, subjects with a BMI ≥ 27 had a markedly increased risk of left atrial appendage thrombus (OR 4.02 CI 95% 1.19-13.55, p=0.025).99

Rate Control

Rate Control

Rate-control treatment is based on pharmacological depression of conduction through the atrioventricular node. Three classes of drugs are commonly used for rate-control treatment: β-blockers, such as metoprolol or bisoprolol, non-dihydropyridine calcium antagonists (verapamil, diltiazem) and digoxin. In the absence of pre-excitation, β-blockers are first-choice drugs to reduce the heart rate. Traditionally, there has been a reluctance to use β-blockers in patients with DM for fear of adverse effects on insulin resistance and an unawareness of hypoglycaemia. However, given the overall benefits of β-blockers in HF and CHD, conditions that are prevalent amongst diabetic patients, the recommendations regarding β-blockade remain the same. Clearly, intolerance in individuals should prompt switching to an alternative.

There is some emerging animal data which suggests that calcium channel blockers, such as a verapamil, may prevent loss of functional β-cell mass.100 It has recently been identified that thioredoxin-interacting protein (TXNIP) may be a potential target to prevent loss of functional β-cell mass. Glucose and DM upregulate β-cell TXNIP expression, and TXNIP overexpression induces β-cell apoptosis. In contrast, genetic ablation of TXNIP promotes endogenous β-cell survival and prevents streptozotocin (STZ) and obesity-induced DM. Xu et al have demonstrated that calcium channel blockers inhibit TXNIP expression in INS-1 cells and human islets. Also, orally administered verapamil reduced TXNIP expression and β-cell apoptosis, enhanced endogenous insulin levels, and rescued mice from STZ-induced DM. Furthermore, verapamil promoted β-cell survival and improved glucose homeostasis and insulin sensitivity in BTBR ob/ob mice. If human studies support these findings then calcium channel blockers may became the drug group of choice in diabetic patients without co-existing HF or CHD.

In patients who fail to respond to rate limiting drugs, non-pharmacological measures such as atrioventricular nodal ablation may be considered.101

Rhythm Control

Up to 50% of patients with recent onset AF revert back to sinus rhythm spontaneously.98 If the patient does not revert spontaneously, they can be considered for either pharmacological or electrical cardioversion, especially for those who remain symptomatic despite adequate ventricular rate control. In patients with structural heart disease, such as CHD and systolic left ventricular dysfunction, class I antiarrhythmic drugs, including flecainide and propafenone, are contraindicated because of the potential increased proarrhythmia risk.98

Amongst diabetic patients this can limit the options for drug therapy due to the higher incidence of HF and CHD. There is no data in the literature to indicate whether commonly used antiarrhythmic medications to achieve cardioversion or maintain sinus rhythm are any less effective amongst diabetic or obese patients and therefore should be considered, bearing in mind the previously mentioned caveats. However, obesity has been implicated in a number of studies as a predictor of failed electrical cardioversion and earlier recurrence of AF.102-104 By virtue of the high prevalence of obesity amongst diabetic patients, as high as 52% in T2DM in some cohorts,105 the more modest success rates in those with BMI >30 should be considered when deciding on management strategy. In those obese patients who fail external DC cardioversion, further options are: higher energy106 antero-posterior positioning of paddles;107 fluoroscopy guided positioning of defibrillation paddles;108 or internal DC cardioversion.109

It should be emphasised that whatever strategy is chosen, the patient must be evaluated for long-term antithrombotic prophylaxis according to his/her risk profile.

Patient-Tailored Therapy

The decision to add rhythm control therapy to the management of AF requires an individual decision and should therefore be discussed at the beginning of AF management and revisited depending on response to treatment/side effects. Before choosing rate control alone as a long-term strategy, the physician should consider how permanent AF is likely to affect the individual patient in the future and how successful rhythm control is anticipated to be. AF related symptom burden is a key determinant in influencing the decision to opt for rate or rhythm control in addition to factors that may influence the likely success of a rhythm control strategy. These include a long history of AF, older age, more severe associated cardiovascular diseases, other associated medical conditions, and enlarged LA size.

The relatively low efficacy of prophylactic antiarrhythmic agents and the incidence of their potentially proarrhythmia effects has promoted the development of non-pharmacological strategies for prevention and control of AF, based on surgical or radiofrequency ablation.

Catheter Ablation of AF in Patients with Diabetes

The increased prevalence of CHD in patients with T2DM often restricts the use of class Ia and Ic antiarrhythmic agents. As such, they may potentially glean a greater symptom benefit from ablation. There are now randomised data evaluating efficacy of catheter ablation in patients with T2DM.110-112 From their study cohort of 263 patients Tang et al compared those with T2DM (n=31) against those without (n=232).112 Although AF recurrence rates were not significantly different between the two groups, the trend suggested higher recurrence in patients with T2DM, 32.3% vs. 22.4% (p=0.24). This trend was to be expected given the important differences in
clinical baseline characteristics: age (62.0 ± 10.8 vs. 56.1 ± 10.6 years, P = 0.004), longer AF history (9.6 ± 9.3 vs. 6.7 ± 6.3 years, p = 0.024), significantly larger left atrium size (41.1 ± 7.8 vs. 38.3 ± 5.8 mm, p = 0.021), HT (58.1 vs. 35.8%, p = 0.018) and structural heart disease (67.7 vs. 43.5%, p = 0.011). Patients with DM also experienced a higher rate of complications, 29.0% vs. 8.2%, p = 0.002). Forleo et al. randomized patients with T2DM to either radiofrequency ablation or anti-arrhythmic therapy. Over a 12-month follow-up period they found that AF recurrence rates were higher in the non-ablation arm (57.1% vs. 20%, p = 0.001). Unlike Tang et al., complication rates were comparable to previous published data for left atrial catheter ablation.

A more recent study compared AF patients with abnormal glucose metabolism (T2DM or IGT) against those without. They found that the substrates for AF differed significantly between the groups: Left atrial (108.4 ± 22.3 vs. 94.0 ± 17.5ms, p <0.001) total activation times were significantly longer in the patients with AF and an abnormal glucose metabolism compared to those normal glucose metabolism. Furthermore, left atrial (1.48±0.74 vs. 2.05±0.78 mV, p<0.001) bipolar voltages were also significantly lower in those with AF and abnormal glucose metabolism. Not unexpectedly, these adverse substrate changes had an impact on AF recurrence rates. Over a follow up period of 18±6.4 months the AF recurrence rate was significantly greater in patients with abnormal glucose metabolism (18.5% vs. 8.0%, p=0.022). Complex fractionated atrial electrograms (CFAE) are well documented to be an important factor in the maintenance of AF in persistent AF. This has led to most electrophysiologists incorporating CFAE ablation as an integral component of ablation in addition to pulmonary vein isolation (PVI) and linear left atrial ablation. CFAE in persistent AF tend to occur in localised areas within the left atrium of slow conduction and low voltage amplitude signals thought to be related to atrial fibrosis. Although there is no data in the literature reporting an increased burden of CFAE in diabetic patients, this is likely, given Chao et al.’s findings of significantly lower left atrial activation times and bipolar voltages in patients with DM/impaired glucose tolerance. There may well be a case for adopting similar ablation strategies in diabetic patients with PAF as are currently used in persistent AF cases, in an effort to reduce AF recurrence.

Catheter Ablation of AF in Obese Patients

Success rates with catheter ablation in obese versus non-obese patients is comparable without a significant increase in complications. Mohanty et al. compared patients with a BMI of <25 and those ≥25 and demonstrated comparable freedom from AF at 12 months (69% vs. 63%, p=0.109, respectively). Interestingly, patients in the obese category reported a greater improvement in quality of life (QoL) scores compared to non-obese patients. This was, at least in part, due to their worse baseline QoL scores. In multivariable analysis BMI ≥25 and baseline QoL were independent predictors of QoL improvement. However, others have found that obesity and metabolic syndrome were independent predictors of late recurrence of AF.

Catheter ablation appears to be an effective treatment in patients with DM, obesity or both and they appear to have more to gain in terms of symptomatic improvement. However, although there is potentially a greater symptom benefit to be gained by obese patients from catheter ablation, and small studies demonstrating comparable procedural risk, in practice, most electrophysiologists will choose not to ablate very obese patients. Catheter ablation in these patients can prove very challenging; venous access is frequently difficult, fluoroscopic imaging is often suboptimal and even sedation/general anaesthesia proves much more challenging.

Upstream Therapies

Increasing evidence has shown that AF development and perpetuation depend on both electrophysiological and structural remodeling of the atrium. Inflammation and oxidative stress have been linked to atrial remodeling and have also been implicated with AF recurrence after catheter ablation. The potential beneficial effects of anti-inflammatory and antioxidant drugs such as statins, RAAS inhibitors and corticosteroids, on AF recurrence after catheter ablation has attracted much interest over the last 5 years. Unfortunately, their potential has remained unfulfilled; angiotensin-converting enzyme inhibitors, ARBs and statins have failed to show any reduction in AF recurrence. Omega-3 polyunsaturated fatty acid supplementation has not been definitively shown to have a positive impact on incidence or recurrence of AF. In fact, the weight of evidence is mostly against any benefit.

A recent 150 patient prospective observational study examined the effect of pioglitazone on the outcome of catheter ablation in patients with paroxysmal AF and T2DM. Consecutive patients undergoing catheter ablation were divided into those who received pioglitazone before ablation or not. 51 patients treated with pioglitazone and 99 control subjects were followed up for at least 15 months after ablation. After a single ablation, sinus rhythm was maintained in 44 patients (86.3%) in the pioglitazone group vs. 70 patients (70.7%) in the control group (p=0.034), without antiarrhythmic drug during a mean follow-up of 22.9 ± 5.1 months. The second ablation was performed in 5 patients (9.8%) from the pioglitazone group and in 24 patients (24.2%) from the control group (p=0.034). Pioglitazone is a peroxisome proliferator activated receptor-gamma (PPARγ) agonist and represents a class of anti-diabetic agents that reduce insulin resistance mainly by activating PPARγ. Accumulating evidence suggests that PPARγ agonists exert modulatory effects on growth factor release, cell proliferation and migration, extracellular matrix remodeling, and cell cycle progression and differentiation. Experimental evidence demonstrates that PPARγ agonists inhibit macrophage activation and the associated inflammatory cytokines as well as suppress superoxide production and induce antioxidant enzymes. Additionally, clinical studies suggest that PPARγ agonists reduce C-reactive protein (CRP) levels in diabetic and non-diabetic patients, independently of glycaemic control. But of course it is important to remember that these drugs are contraindicated in NYHA class III and IV HF and therefore in the context of patients with AF and HF will have limited use. Furthermore because PPARγ agonists cause weight gain, which can increase AF risk, the use of this class of drugs would not be recommended.

Bariatric surgery is the most reliable way of achieving and maintaining significant weight loss in morbibly obese individuals and is being performed in rapidly growing numbers across the globe. Upstream Therapies

Weight loss secondary to bariatric surgery or lifestyle modification may reverse the hypercoagulable state in obesity by a reduction in thrombin generation and PAI-1 and TF levels. Clearly, there is a need for additional studies to further establish the most cost-effective interventions to reduce the pro-thrombotic state and stroke risk.
Conclusions:
Obesity, MetS and DM through a complex interplay of metabolic, inflammatory and neural mechanisms, create an environment conducive to AF and pose unique challenges in the treatment of this common arrhythmia. In addition, the presence of a pro-thrombotic state requires targeted therapeutic interventions if we are to avoid an epidemic of stroke associated with AF. Current evidence challenges the traditional paradigm, which excludes obesity for risk stratification in AF.
